Functions of the skin

2 Approach to the diagnosis of dermatological disease

Introduction

Dermatological diagnosis

Conclusion

3 Bacterial and viral infections

Bacterial infections

Viral infections

4 Fungal infections

Dermatophyte infections

Mycetoma (Madura foot)

Candida infection

Pityriasis versicolor

5 Ectoparasite infections

Scabies

Crusted (Norwegian) scabies

Pediculosis

Papular urticaria

6 Acne, acneiform eruptions and rosacea

Introduction

Acne vulgaris and its variants

Secondary acne

Hidradenitis suppurativa

Acneiform disorders

7 Eczema

Clinical features

Classification

Exogenous eczema

Endogenous eczema

8 Psoriasis

Introduction

Pathology

Clinical patterns of psoriasis

Treatment of psoriasis

Treatment of clinical patterns of psoriasis

Arthropathic psoriasis

Reiter's syndrome

9 Benign and malignant skin tumours

Introduction: classification of skin tumours

Specific tumours

10 Naevi

Introduction

Epithelial and 'organoid' naevi

Melanocytic naevi

Vascular naevi

Other naevi

11 Inherited disorders

The ichthyoses

Collodion baby

Palmoplantar keratoderma

Darier's disease (keratosis follicularis)

Epidermolysis bullosa

Ehlers-Danlos syndrome

Tuberous sclerosis complex

Neurofibromatosis

Peutz-Jeghers syndrome

Hereditary haemorrhagic telangiectasia

(Osler-Weber-Rendu disease)

Basal cell naevus syndrome (Gorlin's syndrome)

Gardner's syndrome

Ectodermal dysplasias

Pseudoxanthoma elasticum

Xeroderma pigmentosum

Acrodermatitis enteropathica
Angiokeratoma corporis diffusum
(Anderson-Fabry disease)
Incontinentia pigmenti
Chromosomal abnormalities

12 Pigmentary disorders

Introduction: normal pigmentary mechanisms
Hypopigmentation
Hyperpigmentation

13 Disorders of the hair and nails

Introduction
Hair abnormalities
Nail abnormalities

14 Bullous disorders

Causes
Rarer blistering diseases

15 Miscellaneous erythematous and papulosquamous disorders, and light-induced skin diseases

Urticaria and angioedema
Erythema multiforme
Exfoliative dermatitis (erythroderma)
Lichen planus
Lichen nitidus

Lichen sclerosus

Pityriasis rosea

Pityriasis lichenoides

Pityriasis rubra pilaris

Miliaria or 'prickly heat'

Pregnancy rashes

Light-induced skin disease

16 Vascular disorders

Leg ulcers

Vasculitis

Other disorders involving blood vessels

17 Connective tissue diseases

Lupus erythematosus

Dermatomyositis

Scleroderma

18 Pruritus

Mechanisms of pruritus

Causes of pruritus

19 Systemic disease and the skin

Endocrine disease

Thyroid disease

Adrenal disease

Rheumatic diseases

Vitamin deficiency

Inflammatory bowel disease

Hyperlipidaemia

Amyloidosis

Sarcoidosis

Liver disease and the skin

Cutaneous manifestations of systemic malignancy

Leukaemia and the skin

Purpura

AIDS and the skin

20 Skin and the psyche

Dermatitis artefacta

Dermatological pathomimicry

Body dysmorphic disorder (dermatological non-disease; dysmorphophobia)

Delusions of parasitosis

Obsessive-compulsive habits

21 Cutaneous drug reactions

Introduction

Drug reaction patterns

Chapter 23: Dermatological emergencies

Matthew Graham-Brown

BSc (Hons) (Birmingham),

MB ChB (Hons) (Leicester Warwick)

Foundation Year 2

West Midlands Deanery

Preface

In this, the tenth edition of *Lecture Notes: Dermatology*, we have updated the text, focusing on recent advances in the knowledge of skin diseases and their treatment. We have also asked a junior doctor working in an acute hospital in the UK to help us add a new chapter on dermatological emergencies.

Numerous tables of salient points provide ready reference but, as in previous editions, we have attempted to create a 'user-friendly' readability.

We hope that the book will be of value not only to medical students, but also to general practitioners, and nurses involved in the care of dermatology patients. We also hope that exposure to *Lecture Notes: Dermatology* will stimulate a deeper interest in this important medical specialty.

Robin Graham-Brown
Tony Burns

Acknowledgements

We are indebted to the late Dr Imrich Sarkany, and to Professor Charles Calnan, under whose guidance we both learned dermatology.

We thank our colleagues in the Dermatology Department in Leicester: Drs Anton Alexandroff, Ian Anderson and Robert Burd, Professor Richard Camp and Drs Karen Harman, Ingrid Helbling, Peter Hutchinson, Graham Johnston, Alex Milligan, Joy Osborne and numerous junior colleagues for creating and sustaining such a stimulating environment in which to work.

It is a pleasure to have been joined for this edition by Matthew Graham-Brown, who has provided an excellent chapter on dermatological emergencies, for which we thank him very much.

We are especially grateful to all the medical students who, over many years, have reminded us of the importance of clarity in communication, and that teaching should be a stimulating and enjoyable experience for everyone concerned.

Finally, we thank the staff at Wiley-Blackwell who have helped us through the editing and production stages.

1

Structure and function of the skin, hair and nails

*Skin, skin is a wonderful thing,
Keeps the outside out and the inside in.*

It is essential to have some background knowledge of the normal structure and function of any organ before you can hope to understand the abnormal. Skin is the icing on the anatomical cake, it is the decorative wrapping paper, and without it not only would we all look rather unappealing, but also a variety of unpleasant physiological phenomena would bring about our demise. You have probably never contemplated your skin a great deal, except in the throes of narcissistic admiration, or when it has been blemished by some disorder, but hopefully by the end of this first chapter you will have been persuaded that it is quite a remarkable organ, and that you are lucky to be on such intimate terms with it.

Skin structure

The skin is composed of two layers, the epidermis and the dermis ([Figure 1.1](#)). The epidermis, which is the outer layer, and its appendages (hair, nails, sebaceous glands and sweat glands), are derived from the embryonic ectoderm. The dermis is of mesodermal origin.

The epidermis

The epidermis is a stratified squamous epithelium, with several well-defined layers. The principal cell type is known as a *keratinocyte*. Keratinocytes, produced by cell division in the deepest layer of the epidermis (basal layer), are carried towards the skin surface, undergoing in transit a complex series of morphological and biochemical changes known as *terminal differentiation* (keratinization) to produce the surface layer of tightly packed dead cells (stratum corneum or horny layer) which are eventually shed. In health the rate of production of cells matches the rate of loss so that epidermal thickness is constant. Epidermal kinetics are controlled by a number of growth stimulators and inhibitors.

The components of this differentiation process are under genetic control and mutations in the controlling genes are responsible for a variety of diseases.

So-called *intermediate filaments*, present in the cytoplasm of epithelial cells, are a major component of the cytoskeleton. They contain a group of fibrous proteins known as keratins, each of which is the product of a separate gene. Pairs of keratins are characteristic of certain cell types and tissues. The mitotically active keratinocytes in the basal layer express the keratin pair K5/K14, but during the differentiation process expression of K5/K14 is down-regulated and that of K1/K10 is induced.

Figure 1.1 The structure of the skin.

As cells reach the higher layers of the epidermis, keratin filaments aggregate into keratin fibrils under the influence of a protein known as *filag-grin* (filament-aggregating protein)—this is derived from its precursor *profilaggrin*, present in *keratohyalin granules* which constitute the granules in the granular layer. Derivatives of the proteolysis of filaggrin are major components of natural moisturizing factor (NMF) which is important in the maintenance of epidermal hydration. Loss-of function mutations in *FLG*, the gene encoding filaggrin, underlie ichthyosis vulgaris and strongly predispose to atopic eczema; carriers of these mutations have reduced levels of NMF in the stratum corneum.

In the final stages of terminal differentiation, the plasma membrane is replaced by the *cornified cell envelope*, composed of several proteins the production of which is also under genetic control. Cells that have developed this envelope and have lost their nucleus and organelles constitute the *corneocytes* of the stratum corneum.

Look at the layers more closely ([Figure 1.2](#)). The basal layer, which is one to three cells thick, is anchored to a basement membrane (see below) that lies between the

epidermis and dermis. Interspersed among the basal cells are melanocytes—large dendritic cells derived from the neural crest—that are responsible for melanin pigment production. Melanocytes contain cytoplasmic organelles called melanosomes, in which melanin is synthesized from tyrosine. The melanosomes migrate along the dendrites of the melanocytes and are transferred to the keratinocytes in the prickle cell layer. In white people the melanosomes are grouped together in membrane-bound *melanosome complexes*, and they gradually degenerate as the keratinocytes move towards the surface of the skin. The skin of black people contains the same number of melanocytes as that of white people, but the melanosomes are larger, remain separate and persist through the full thickness of the epidermis. The main stimulus to melanin production is ultraviolet (UV) radiation. Melanin protects the cell nuclei in the epidermis from the harmful effects of UV radiation. A suntan is a natural protective mechanism, not some God-given cosmetic boon created so that you can impress the neighbours on your return from an exotic foreign trip! Unfortunately, this does not appear to be appreciated by the pale, pimply, lager-swilling advert for British manhood who dashes onto the beach in Ibiza and flash fries himself to lobster thermidor on day one of his annual holiday.

Skin neoplasia is extremely uncommon in dark-skinned races because their skin is protected from UV damage by the large amounts of melanin that it contains. However, individuals with albinism are predisposed to skin cancer because their production of melanin is impaired and they are therefore without its protective influence.

Above the basal layer is the prickle cell/spinous layer. This acquires its name from the spiky appearance produced by the intercellular bridges (desmosomes) that connect adjacent cells. Important in cell-cell adhesion are several

protein components of desmosomes (including cadherins [desmogleins and desmocollins] and plakins). Production of these is genetically controlled, and abnormalities have been detected in some human diseases.

Figure 1.2 The epidermis.

Scattered throughout the prickle cell layer are Langerhans' cells. These dendritic cells contain characteristic racquet-shaped 'Birbeck' granules. Langerhans' cells are probably modified macrophages, which originate in the bone marrow and migrate to the epidermis. They are the first line of immunological defence against environmental antigens (see below).

Above the prickle cell layer is the granular layer, which is composed of flattened cells containing the darkly staining keratohyalin granules. Also present in the cytoplasm of cells in the granular layer are organelles known as lamellar granules (Odland bodies). These contain lipids and enzymes, and they discharge their contents into the intercellular spaces between the cells of the granular layer and stratum corneum—providing the equivalent of 'mortar' between the cellular 'bricks', and contributing to the barrier function of the epidermis.

The cells of the stratum corneum are flattened, keratinized cells that are devoid of nuclei and cytoplasmic organelles. Adjacent cells overlap at their margins, and this locking together of cells, together with intercellular lipid, forms a very effective barrier. The stratum corneum varies in thickness according to the region of the body. It is thickest on the palms of the hands and soles of the feet. The stratum corneum cells are gradually abraded by daily wear and tear. If you bathe after a period of several days' avoidance of water (a house without central heating, in mid-winter, somewhere in the Northern Hemisphere, is ideal for this experiment), you will note that as you towel yourself you are rubbing off small balls of keratin—which has built up because of your unsanitary habits. When a plaster cast is removed from a fractured limb after several weeks *in situ* there is usually a thick layer of surface keratin, the removal of which provides hours of absorbing occupational therapy.

[Figure 1.3](#) shows the histological appearance of normal epidermis.

The basement membrane zone

This is composed of a number of layers, and it is important to have some knowledge of these because certain diseases are related to abnormalities in the layers. The basic structure is shown in [Figure 1.4](#). Basal keratinocytes are attached by *hemidesmosomes* to the epidermal side of the membrane, and these have an important role in maintaining adhesion between the epidermis and dermis. The basement membrane is composed of three layers: lamina lucida (uppermost), lamina densa and lamina fibroreticularis. A system of *anchoring filaments* connects hemidesmosomes to the lamina densa, and *anchoring fibrils*, which are closely associated with collagen in the upper dermis, connect the lamina densa to the dermis beneath.

The hemidesmosome/anchoring filament region contains autoantigens targeted by autoantibodies in immunobullous disorders (including bullous pemphigoid, pemphigoid gestationis, cicatricial pemphigoid and linear IgA bullous dermatosis—see Chapter 14), hence the subepidermal location of blistering in these disorders.

Figure 1.3 Section of skin stained with haematoxylin and eosin, showing the appearance of a normal epidermis. ‘Rete ridges’ (downward projections of the epidermis) interdigitate with ‘dermal papillae’ (upward projections of the dermis).

The inherited blistering diseases (see Chapter 14) occur as a consequence of mutations in genes responsible for components of the basement membrane zone, e.g. epidermolysis bullosa simplex, in which splits occur in the basal keratinocytes, is related to mutations in genes coding for keratins 5 and 14, and dystrophic epidermolysis bullosa, in which blistering occurs immediately below the lamina densa, is related to mutations in a gene coding for type VII collagen, the major component of anchoring fibrils.

Epidermal appendages

The eccrine and apocrine sweat glands, the hair and sebaceous glands, and the nails, constitute the epidermal appendages.

Eccrine sweat glands

Eccrine sweat glands are important in body temperature regulation. A human has between two and three million eccrine sweat glands covering almost all the body surface. They are particularly numerous on the palms of the hands and soles of the feet. Each consists of a secretory coil deep in the dermis, and a duct that conveys the sweat to the surface. Eccrine glands secrete water, electrolytes, lactate, urea and ammonia. The secretory coil produces isotonic sweat, but sodium chloride is reabsorbed in the duct so that sweat reaching the surface is hypotonic. Patients with cystic fibrosis have defective reabsorption of sodium chloride, and rapidly become salt depleted in a hot environment. Eccrine sweat glands are innervated by the sympathetic nervous system, but the neurotransmitter is acetylcholine.

Figure 1.4 Structure of the basement membrane zone.

Apocrine sweat glands

Apocrine sweat glands are found principally in the axillae and anogenital region. Specialized apocrine glands include the wax glands of the ear and the milk glands of the breast. Apocrine glands are also composed of a secretory coil and a duct, but the duct opens into a hair follicle, not directly on to the surface of the skin. Apocrine glands produce an oily secretion containing protein, carbohydrate, ammonia and lipid. These glands become active at puberty, and secretion

is controlled by adrenergic nerve fibres. Pungent axillary body odour (axillary bromhidrosis) is the result of the action of bacteria on apocrine secretions. In some animals apocrine secretions are important sexual attractants, but the average human armpit provides a different type of overwhelming olfactory experience.

Hair

Hairs grow out of tubular invaginations of the epidermis known as follicles, and a hair follicle and its associated sebaceous glands are referred to as a 'pilosebaceous unit'. There are three types of hair: fine, soft *lanugo* hair is present *in utero* and is shed by the eighth month of fetal life; *vellus* hair is the fine downy hair that covers most of the body except those areas occupied by terminal hair; and thick and pigmented *terminal* hair occurs on the scalp, eyebrows and eyelashes before puberty—after puberty, under the influence of androgens, secondary sexual terminal hair develops from vellus hair in the axillae and pubic region, and on the trunk and limbs in men. On the scalp, the reverse occurs in male-pattern balding—terminal hair becomes vellus hair under the influence of androgens. In men, terminal hair on the body usually increases in amount as middle age arrives, and hairy ears and nostrils, and bushy eyebrows, are puzzling accompaniments of advancing years. One struggles to think of any biological advantage conferred by exuberant growth of hair in these sites.

Hair follicles extend into the dermis at an angle (see [Figure 1.1](#)). A small bundle of smooth muscle fibres, the arrector pili muscle, is attached to the side of the follicle. Arrector pili muscles are supplied by adrenergic nerves, and are responsible for the erection of hairs in the cold or during emotional stress ('goose flesh', 'goose pimples', horripilation). The duct of the sebaceous gland enters the

follicle just above the point of attachment of the arrector pili muscle. At the lower end of the follicle is the hair bulb, part of which, the hair matrix, is a zone of rapidly dividing cells that is responsible for the formation of the hair shaft. Hair pigment is produced by melanocytes in the hair bulb. Cells produced in the hair bulb become densely packed, elongated and arranged parallel to the long axis of the hair shaft. They gradually become keratinized as they ascend in the hair follicle.

The main part of each hair fibre is the cortex, which is composed of keratinized spindle-shaped cells ([Figure 1.5](#)). Terminal hairs have a central core known as the medulla, consisting of specialized cells that contain air spaces. Covering the cortex is the cuticle, a thin layer of cells that overlap like the tiles on a roof, with the free margins of the cells pointing towards the tip of the hair. The cross-sectional shape of hair varies with body site and race. Negroid hair is distinctly oval in cross-section, and pubic, beard and eyelash hairs have an oval cross-section in all racial types. Caucasoid hair is moderately elliptical in cross section and mongoloid hair is circular.

The growth of each hair is cyclical—periods of active growth alternate with resting phases. After each period of active growth (anagen) there is a short transitional phase (catagen), followed by a resting phase (telogen), after which the follicle reactivates, a new hair is produced and the old hair is shed. The duration of these cyclical phases depends on the age of the individual and the location of the follicle on the body. The duration of anagen in a scalp follicle is genetically determined, and ranges from 2 to more than 5 years. This is why some women can grow hair down to their ankles, whereas most have a much shorter maximum length. Scalp hair catagen lasts about 2 weeks and telogen from 3 months to 4 months. The daily growth rate of scalp hair is approximately 0.45 mm. The activity of each follicle

is independent of that of its neighbours, which is fortunate, because, if follicular activity were synchronized, as it is in some animals, we would be subject to periodic moults, thus adding another dimension to life's rich tapestry. At any one time approximately 85% of scalp hairs are in anagen, 1% in catagen and 14% in telogen. The average number of hairs shed daily is 100. In areas other than the scalp anagen is relatively short—this is also fortunate, because, if it were not so, we would all be kept busy clipping eyebrows, eyelashes and nether regions.

Figure 1.5 The structure of hair.

It is a myth that shaving increases the rate of growth of hair and that it encourages the development of 'thicker' hair; nor does hair continue growing after death—shrinkage of soft tissues around the hair produces this illusion.

Human hair colour is principally dependent on two types of melanin: eumelanins in black and brown hair, and phaeomelanins in red, auburn and blond hair.

Greying of hair (canities) is the result of a decrease in tyrosinase activity in the melanocytes of the hair bulb. The age of onset of greying is genetically determined, but other factors may be involved such as autoimmunity—premature greying of the hair is a recognized association of pernicious anaemia. The phenomenon of 'going white overnight' has been attributed to severe psychological stress—it is said that the hair of Thomas Moore and Marie Antoinette turned

white on the night before their executions. However, this is physically impossible unless related to the washing out of temporary hair dye, but it might occur over a period of a few days or weeks as a result of alopecia areata occurring in an individual with a mixture of white and pigmented hair in whom there was selective loss of pigmented hair.

Sebaceous glands

Sebaceous glands are found everywhere on the skin apart from the hands and feet. They are particularly numerous and prominent on the head and neck, the chest and the back. Sebaceous glands are part of the pilosebaceous unit, and their lipid-rich product (sebum) flows through a duct into the hair follicle. They are holocrine glands—sebum is produced by disintegration of glandular cells rather than an active secretory process. Modified sebaceous glands that open directly on the surface are found on the eyelids, lips, nipples, glans penis and prepuce, and the buccal mucosa (Fordyce spots).

Sebaceous glands are prominent at birth, under the influence of maternal hormones, but atrophy soon after, and do not enlarge again until puberty. Enlargement of the glands and sebum production at puberty are stimulated by androgens. Growth hormone and thyroid hormones also affect sebum production.

Nails

A nail is a transparent plate of keratin derived from an invagination of epidermis on the dorsum of the terminal phalanx of a digit ([Figure 1.6](#)). The nail plate is the product of cell division in the nail matrix, which lies deep to the proximal nail fold, but is partly visible as the pale ‘half-moon’ (lunula) at the base of the nail. The nail plate adheres firmly to the underlying nail bed. The cuticle is an extension of the horny layer of the proximal nail fold on to the nail

plate. It forms a seal between the nail plate and proximal nail fold, preventing penetration of extraneous material.

Figure 1.6 The nail.

Nail growth is continuous throughout life, but is more rapid in youth than in old age. The average rate of growth of fingernails is approximately 1 mm/week, and the time taken for a fingernail to grow from matrix to free edge is about 6 months. Nails on the dominant hand grow slightly more rapidly than those on the non-dominant hand. Toenails grow at one-third the rate of fingernails, and take about 18 months to grow from matrix to free edge.

Many factors affect nail growth rate. It is increased in psoriasis, and may be speeded up in the presence of inflammatory change around the nail. A severe systemic upset can produce a sudden slowing of nail growth, causing a transverse groove in each nail plate. These grooves, known as Beau's lines, subsequently become visible as the nails grow out. Nail growth may also be considerably slowed in the digits of a limb immobilized in plaster.

The dermis

The dermis is a layer of connective tissue lying beneath the epidermis, and forms the bulk of the skin. The dermis and epidermis interdigitate via downward epidermal projections (rete ridges) and upward dermal projections (dermal papillae) (see [Figures 1.1](#) and [1.3](#)). The main feature of the dermis is a network of interlacing fibres, mostly collagen, but with some elastin. These fibres give the dermis great strength and elasticity. The collagen and elastin fibres, which are protein, are embedded in a ground substance of mucopolysaccharides (glycosaminoglycans).

The main cellular elements of the dermis are fibroblasts, mast cells and macrophages. Fibroblasts synthesize the connective tissue matrix of the dermis, and are usually found in close proximity to collagen and elastin fibres. Mast cells are specialized secretory cells present throughout the dermis, but they are more numerous around blood vessels and appendages. They contain granules the contents of which include mediators such as histamine, prostaglandins, leukotrienes, and eosinophil and neutrophil chemotactic factors. Macrophages are phagocytic cells that originate in the bone marrow, and they act as scavengers of cell debris and extracellular material. The dermis is also richly supplied with blood vessels, lymphatics, nerves and sensory receptors. Beneath the dermis, a layer of subcutaneous fat separates the skin from underlying fascia and muscle.

Dermatoglyphics

Fingerprints, the characteristic elevated ridge patterns on the fingertips of humans, are unique to each individual. The fingers and toes, and the palms and soles, are covered with a system of ridges that form patterns. The term 'dermatoglyphics' is applied to the configuration of the ridges. If you look closely at your hands you will see these

tiny ridges, which are separate from the skin creases. On the tips of the fingers there are three basic patterns: arches, loops and whorls ([Figure 1.7](#)). The loops are subdivided into ulnar or radial, depending on whether the loop is open to the ulnar or radial side of the hand. A triangular intersection of these ridges is known as a triradius, and these triradii are present not only on fingertips, but also at the base of each finger, and usually on the proximal part of the palm.

Not only are the ridge patterns of fingerprints useful for the identification and conviction of those who covet their neighbours' goods, but characteristic dermatoglyphic abnormalities frequently accompany many chromosomal aberrations.

[Figure 1.7](#) Dermatoglyphics: (a) arch; (b) loop; (c) whorl.

Functions of the skin

Skin is like wax paper that holds everything in without dripping.

Art Linkletter, A Child's Garden of Misinformation, 1965

It is obvious from the complex structure of the skin that it is not there simply to hold all the other bits of the body together. Some of the functions of skin are as shown in the box.

Skin functions
